Keywords: Inverter drives, multi-loop-control, active damping, system input limitation, nonlinear filters.

1. INTRODUCTION

Today, motor inverters in the kW domain typically are implemented using silicon (Si) based insulated gate bipolar transistors (Si-IGBT) operating in pulse width modulation (PWM) mode at switching frequencies up to 20 kHz. During the past few years, however, wide-bandgap switching devices like GaN- and SiC-MOSFETs have been significantly improved, especially concerning voltage capability of GaN devices. Due to the low switching- and also low on-state losses of GaN MOSFETs in comparison to Si-IGBTs, motor inverters with rather high switching frequencies but also high efficiency rates can be achieved (Shirabe and Swamy, 2012). However, the occurring high switching speed of the transistors with rise times in the range of 10 ns also create some crucial issues for motor applications caused by high du/dt rates.

To avoid and reduce negative effects of high-speed switching, the GaN inverter has to be extended by a filter system, with GaN power stage (switching frequency 100 kHz), active damped filter and a 3-phase motor as load.

As described in (Maislinger et al., 2017), a single equivalent circuit of the inverter can be found, (c.f., Fig. 2a), which shows the behavior. The motor, which operates as inverter load, is considered by its resistance \( R_M \), inductance \( L_M \), (which is at least ten times higher than \( L_1 \)) and by the rotational speed proportional induced voltage \( u_{emf} \), which acts in the system as a disturbance value. In case of a motor inverter controller parameters will be discussed in an upcoming paper, because here, the focus lies on the active damping scheme. Therefore, a mathematical model which represents the the physical properties of the filter and the motor as a load is implemented. Nevertheless, as illustrated in the following section inverter voltage limitations and nonlinearities of passive filter elements have negative influence on the chosen active damping scheme.

Fig. 1. Schematic concept of the proposed motor inverter with GaN power stage (switching frequency 100 kHz), active damped filter and a 3-phase motor as load.

GaN Power Stage Active-Damped Filter

Fig. 2. (a) Single equivalent circuit of the inverter. (b) Plant dynamic model.

As described in (Maislinger et al., 2017), a single equivalent circuit can be found, (c.f., Fig. 2a), which shows the influence of the feedback of the capacitor current on the transfer function of the inverter. Therefore, the GaN power stage block has an assumed transfer function of gain \( \nu = 1 \). Furthermore, only a single stage filter is considered. The feedback gain \( k \) can be adjusted to obtain a desired filter behavior. The motor, which operates as inverter load, is considered by its resistance \( R_M \), inductance \( L_M \), (which is at least ten times higher than \( L_1 \)) and by the rotational speed proportional induced voltage \( u_{emf} \), which acts in the system as a disturbance value. In case of a motor inverter...
leads to an expression of the active damping parameter $k$ in the form

$$k = \frac{2s}{\omega_0} \left( \frac{L_1 + L_M}{C_1 L_M} \right),$$

which guarantees a well damped system behavior.

### 2.1 System Input Limitation

For the investigated inverter, in case of a large step-change in the desired motor current $i^*$ the system input $u_i$ is limited to $\pm U$ (whereby $U$ corresponds to the half of the DC-link voltage) as illustrated in Fig. 3a (switch $S_1$ is in position $S_1 = 0$). Therefore, the implemented active damping scheme is ineffective, since no control margin is available to counteract the excitation of the filter resonance. This phenomenon can be decreased if an additional output limiter is adapted next to the controller ($S_1 = 1$), which guarantees a buffer for the active damping scheme.

### 2.2 Nonlinearities of Passive Filter Elements

To consider the nonlinearities of the passive filter elements in the model, the function $G_s$ of Fig. 2b has to be replaced by Fig. 3b. The values of the lookup tables come from data sheets that correspond to a Sendust powder core with a permeability of 60 for $L_1(i)$ and an Archshield ceramic capacitor with 330 nF, 500 V for $C_1(u)$ (KEMET, 2017). As mentioned above in (3), the optimal active damping parameter $k$ is a function of the passive filter elements $L_1$ and $C_1$. However, by measuring the capacitor filter current $i_{C1}$ nonlinearities of $L_1$ and $C_1$ seem to have only small influences on the active damping mechanism of the proposed inverter as illustrated in Fig. 4b. But, if the effect of a time delay caused by measuring the filter current is also considered ($S_2 = 1$), the impact of nonlinear filter elements is crucial. In Fig. 4b, a time delay $T_d$ of 5 ns is assumed, which corresponds to half a period at a switching frequency of 100 kHz. For higher time delays in the range of a full switching period the system becomes unstable.

### 3. CONCLUSION

The paper gives a brief overview about the impacts of nonlinearities and input limitations on wide-bandgap inverters with an active damped LC-filter. It is shown that by using a further limiter after the controller output, the functionality of the active damping scheme remains present, independent of the controller output. Furthermore, nonlinearities and time delays in capacitor current measurement can lead to an unstable behavior of the dynamic plant. The negative time delay effect can be neglected, if a linear observer-based model is used to calculate the capacitor filter current instead of the measurement. The effect of nonlinear filter elements on the control concept with the observer-based model is under investigation.
